Peanut Science (1984) 11:98-102

Evaluation of the Insecticide Chlorpyrifos for Activity Against Southern Stem Rot of Peanut

A. S. Csinos¹

ABSTRACT

Chlorpyrifos, a soil insecticide reported to have activity in controlling southern stem rot of peanuts, was evaluated in an area heavily infested with the southern stem rot pathogen Sclerotium rolfsii Sacc. over a three year period (1981-1983). Chlorpyrifos 4E at 0, 1.12 or 2.24 kg ai/ha was applied preplant incorporated broadcast followed by 0, 1.12 or 2.24 kg ai/ha chlorpyrifos 15G or 4E at pegging in a 40 cm band over the row. Combinations of chlorpyrifos and PCNB were also evaluated as a formulated granule and as concomitantly applied separate materials. Disease loci were enumerated during the season and at inverting and yields were determined for plots. Chlorpyrifos alone did not significantly decrease disease in any of the tests over the three year period at any rate or method of application tested. A PCNB + chlorpyrifos (11.2-2.24 kg ai/ha) combination granule and the two chemicals applied concomitantly were as effective as PCNB + fensulfothion (11.2-3.36 kg ai/ha) in reducing disease and increasing yield. Potential niches for the use of chlorpyrifos in reducing southern stem rot are discussed.

Key Words: White mold, Sclerotium rolfsii.

Southern stem rot of peanuts caused by Sclerotium rolfsii Sacc. is one of the most serious soil-borne diseases of peanut. The disease causes an estimated 10% loss of crop value or about \$40 million loss each year in Georgia (10). Recommended control of the disease in Georgia includes a combination of cultural practices such as rotation with a grass crop, deep plowing to bury crop litter, avoidance of dirting of plants during cultivation and the use of PCNB in combination with fensulfothion or ethoprop applied at pegging time (8,9).

Several researchers have reported antifungal activity of nematicides and insecticides against soil-borne pathogens associated with peanut (1,2,3,5,6,8). Backman and Hammond (1) showed that the 4EC formulation of chlorpyrifos suppressed the growth of Sclerotium rolfsii in vitro and reduced southern stem rot of peanut in the field. They reported a synergism between the active and inert ingredients in the EC formulation in laboratory studies, and suggested that the granular formulation would show lower activity, because of the absence of the emulsifier in the granular formulation. The use of a pesticide such as chlorpyrifos that has both insecticidal and fungicidal activity, would be important in peanut culture because of the reduced applications of pesticides required. Non target effects have been cited frequently (1,2,3,5,6,7) but few have been exploited for the benefit of commercially grown crops.

This study further evaluates the antifungal activity of chlorpyrifos under field conditions. Rates of chlorpyri-

fos, methods of application, application timing and both emulsifiable concentrate and granule formulation were evaluated for control of southern stem rot of peanut. A combination of chlorpyrifos with PCNB applied in a single formulated product or concomitantly as separate products was also evaluated.

Materials and Methods

The field plot area was a Tifton loamy sand infested with Sclerotium rolfsii. In 1982 and 1983, when peanuts were 30 days old, infested soil containing sclerotia, from a diseased lupin field, was used to further infest the soil with S. rolfsii. Approximately 50 sclerotia in sand were distributed over each plot. Experimental design was a randomized complete block with four replications. Plots were two rows, 7.6 m long and 0.7 m apart. Chemical treatments were: chlorpyrifos 4E applied at 1.12 or 2.24 kg ai/ha preplant incorporated or at pegging; chlorpyrifos 15G at 1.12 or 2.24 kg ai/ha at pegging; PCNB 10G applied at 11.2 kg ai/ha as a single application or split into two equal applications at pegging and three weeks later; PCNB + chlorpyrifos 10-2G at 11.2 + 2.24 kg ai/ha as a single application or split into two; and PCNB-fensulfothion 10-3G applied at 11.2 + 3.36 kg ai/ha at pegging. Chlorpyrifos formulations were supplied by Dow Chemical USA, Midland, Mich., and PCNB and combination materials were supplied by Olin Corp., Little Rock, Ark. Preplant incorporated (PPI) treatments were applied with a tractor mounted sprayer-rototiller before planting and incorporated up to 15 cm deep. Peanut, Arachis hypogaea L., cultivar Florunner was seeded at the rate of 112 kg/ha on May 5, 1981, May 7, 1982, and May 12, 1983. At pegging treatments were applied over the row in a 40 cm band. Granules were preweighed and applied with salt shaker-like containers, and emulsifiable concentrates were applied with a knapsack sprayer in 466 L of spray/ ha. Recommended fertilization, cultural practices, and insect and foliar disease control were followed. Water was applied by overhead irrigation as required when water stress was visually apparent. Numbers of disease loci were counted twice during the season and at inverting. A disease locus consisted of a 30 cm section of row or less, infected with S. rolfsii as described by Rodriguez-Kabana et al. (4). In 1982 and 1983 plots were given a severity rating of 0.1-1.0, where 0.1 = visable damage and 1.0 = all nuts decayed or missing from crown of inverted peanuts. A disease index was calculated as follows:

DI = No. disease loci at digging x severity rating Plots were inverted 140, 132 and 145 days after planting in 1981, 1982 and 1983, respectively. After plots were harvested, peanuts were dried and weighed and yields determined. Data were analyzed by analysis of variance, Duncan's multiple range test and regression.

Results

Peanuts treated with combinations of PCNB and chlorpyrifos or fensulfothion tended to have the best control of disease and the highest yields (Tables 1,2,3,4). In 1981 (Table 1) yields were relatively low, but disease pressure was moderate. Although significant differences among treatments did not occur in disease at 87 days post planting, plots treated with chlorpyrifos 15G alone had less disease than chlorpyrifos 4E + PCNB at 120 days post planting. However, at 140 days post plant (at inverting) no differences for numbers of disease loci among treatments were detected. Plots treated with chlorpyrifos (4E or 15G) + PCNB had higher yields than the control or chlorpyrifos 4E or 15G alone at 2.24 kg ai/ha.

In 1982, peanuts treated with PCNB + chlorpyrifos as a single or split application had less disease than the control 112 days post planting and at inverting; and smaller disease indices than the control plots (Table 2). Peanuts in all treatments had less disease 131 and 132 days post plant (before and after inverting) and had

 $^2\mathrm{Disease}$ loci were counted 87, 120 and 140 days post plant. The last evaluation was made after inverting.

³Means in columns followed by common letters are not significantly different according to Duncan's multiple range test, <u>P</u> = 0.05.

smaller disease indices than the control (Table 2). Only PCNB + chlorpyrifos as a split application increased yield. Disease loci counts taken 112 and 131 days post plant were correlated negatively (P=0.01) with yield at r = -0.43 and -0.41, respectively. Disease loci counted 132 days post plant (at inverting) and disease indices were not significantly correlated with yield.

In 1982 in a chlorpyrifos formulation rate and method of application experiment (Table 3), none of the treatments decreased disease or increased yield over the control. There was no particular trend in increased disease control with either of the chlorpyrifos formulations. Disease loci counted 112 and 132 days post plant and disease index were negatively correlated (P = 0.01) with yield at -0.45, -0.51 and -0.39, respectively.

In 1983, no treatment reduced numbers of disease loci over the control (Table 4). However, plots treated with chlorpyrifos 4E at 2.24 kg ai/ha applied before planting plus chlorpyrifos 15G 1.12 kg ai/ha applied at pegging and PCNB + chlorpyrifos 10-2G at 11.2 + 2.24 kg ai/ha applied at pegging increased yield. Disease loci counts taken 120 and 145 days post planting were negatively correlated (P = 0.01) with yield at -0.40, and -0.35, respectively. In all tests disease loci were higher when counted at digging then just before digging. This was because of increased visibility on inverted peanuts.

Pods evaluated in 1983, indicated a general low level of insect damage. Other tests were not evaluated for insect damage, but obvious insect damage was not observed. No nematode damage occurred in any year.

Discussion

Generally, all the materials tested performed poorly, or were very variable in performance. This is basically a function of the disease organism which is active over several months of the peanut growing season. No fungicides control the disease, however, some reduce damage (2,8,9).

Work by Backman and Hammond (1) suggested that the emulsifiable concentrate formulation of chlorpyrifos would be a better fungicide than the granule formulation for control of southern stem rot of peanuts. This

Table 4. Evaluation of chlorpyrifos and PCNB for control of Sclerotium rolfsii and effect on yield, 1983.

¹PPI is preplant incorporated on May 12 and peg is at pegging application on July 6, 1983.

 2 Disease loci were counted 118 and 145 days post seeding and again after inverting 145 days post seeding.

³Disease index is disease loci counted post inverting multiplied by a subjective severity rating.

⁴Means followed by same letter are not significantly different according to Duncan's multiple range test, <u>P</u> = 0.05.

conclusion was based on laboratory data which indicated a synergistic effect between chlorpyrifos and the emulsifier. These field trials do not support this contention. Numbers of disease loci and yield were similar for both formulations in all three years of evaluation across several rates and application methods (Tables 1,3,4). Although there were trends in disease reduction and increases in yield with chlorpyrifos, the insecticide did not significantly reduce southern stem rot of peanut. Yield was increased in one of three years tested at a total rate of 3.36 kg ai/ha; however, a total rate of 4.48 kg ai/ha did not (Table 4).

The combination of PCNB and chlorpyrifos applied as a formulated granule or applied concomitantly as separate materials was as effective as PCNB + fensulfothion in reducing disease and increasing yield. PCNB alone was effective in reducing disease only in 1982 in one test (Table 2), but not in two other tests (Table 3,4). Yield was not increased by PCNB alone in any test.

Rodriguez-Kabana *et al.* (5,6) have demonstrated antifungal activity of both ethoprop and fensulfothion at relatively high rates of 8.97 and 8.9 kg ai/ha, respectively. The activity of chlorpyrifos was not as consistent as they were for ethoprop and fensulfothion (5,6). However, considerably lower rates of chlorpyrifos (1.12-4.48 kg ai/ha) were used (Tables 2,3,4). The widespread use of insecticides in Georgia on peanuts (11) underscores the importance of understanding their non-target effects in peanut fields. Our studies did not indicate that chlorpyrifos alone should be used as a specific treatment for control of Southern stem rot of peanut. However, because chlorpyrifos is recommended for control of several soil insects (11) and application timing for both insect control and southern stem rot control coincide, under light infestations of *Sclerotium rolfsii* chlorpyrifos may be effective in reducing southern stem rot of peanuts. No chemical treatments are available which control southern stem rot of peanut. However, chemical combinations for reduction of the disease are recommended in Georgia including a combination of chlorpyrifos and PCNB (8,9,10).
